SUCCESSFUL ANTIRETROVIRAL therapy (ART) is associated with dramatic decreases in AIDS-defining conditions and their associated mortality. Expansion of treatment options and evolving knowledge require revision of guidelines for the initiation and long-term management of ART in adults with HIV infection.

Since the 2008 International AIDS Society–USA ART guidelines,1 new data have emerged regarding timing of therapy, optimal regimen choices, and monitoring. There are also issues of special relevance to circumstances such as pregnancy, hepatitis virus coinfections, kidney disease, cardiovascular disease, and primary HIV infection.

Analyses of clinical trials and epidemiologic cohorts have shed light on the role of ART in mitigating serious non-AIDS events associated with uncontrolled HIV replication. Newer drugs are better understood in terms of efficacy, toxicity, and potential uses. New data also suggest a role for ART in the prevention of HIV transmission.

METHODS

The panel was convened in 1995 to develop evidence-based recommendations for ART for HIV-infected adults in developed-world settings.2 Members are appointed by International AIDS Society–USA according to clinical and research expertise. Current panel members do not participate in pharmaceutical marketing or promotional activities (eg, speakers’ bureaus, industry satellites) during tenure on the panel. The current panel convened in January 2010 and met weekly in person or by teleconference. Data published or presented in specific scientific meetings since the last report1 of the panel were considered in preparing this update.

Context Recent data regarding the consequences of untreated human immunodeficiency virus (HIV) infection and the expansion of treatment choices for antiretroviral-naive and antiretroviral-experienced patients warrant an update of the International AIDS Society–USA guidelines for the use of antiretroviral therapy in adults with HIV infection.

Objectives To provide updated recommendations for management of HIV-infected adults, using antiretroviral drugs and laboratory monitoring tools available in the international, developed-world setting. This report provides guidelines for when to initiate antiretroviral therapy, selection of appropriate initial regimens, patient monitoring, when to change therapy, and what regimens to use when changing.

Data Sources and Study Selection A panel with expertise in HIV research and clinical care reviewed relevant data published or presented at selected scientific conferences since the last panel report through April 2010. Data were identified through a PubMed search, review of scientific conference abstracts, and requests to antiretroviral drug manufacturers for updated clinical trials and adverse event data.

Data Extraction and Synthesis New evidence was reviewed by the panel. Recommendations were drafted by section writing committees and reviewed and edited by the entire panel. The quality and strength of the evidence were rated and recommendations were made by full panel consensus.

Conclusions Patient readiness for treatment should be confirmed before initiation of antiretroviral treatment. Therapy is recommended for asymptomatic patients with a CD4 cell count >500/µL, for all symptomatic patients, and those with specific conditions and comorbidities. Therapy should be considered for asymptomatic patients with CD4 cell count >500/µL. Components of the initial and subsequent regimens must be individualized, particularly in the context of concurrent conditions. Patients receiving antiretroviral treatment should be monitored regularly; treatment failure should be detected and managed early, with the goal of therapy, even in heavily pretreated patients, being HIV-1 RNA suppression below commercially available assay quantification limits.
were considered (eFigure, available at http://www.jama.com). Data on file and personal communications were not considered except for data and safety monitoring board reports and US Food and Drug Administration alerts.

For identification of evidence, one member (P.A.V.) conducted a PubMed search of reports published since the last update. Search terms were HIV and antiretroviral, limited to humans, clinical trials, meta-analyses, randomized controlled trials, reviews, English, and adult, and yielded 582 citations. Of those, 194 citations were selected for review, eliminating those not relevant to adult care in resource-rich settings. Section teams identified abstracts from scientific conferences. Drug manufacturers were asked to provide published or presented data on updated clinical trials and adverse events for their products.

Section team leaders (J.A.A., P.C., J.S.G.M., G.R., and A.T.) summarized section consensus for group review and discussion. The quality and strength of the evidence were rated for each recommendation (eBox). Final recommendations were by full panel consensus.

WHEN TO START
Established HIV-1 Infection
Deciding to start ART requires weighing the benefits of treatment on morbidity and mortality against its risks, including toxicity, resistance, drug interactions, and the costs and inconvenience of lifelong treatment. Sustained viral suppression restores and preserves immunologic function, decreasing opportunistic diseases and mortality. The patient must be ready and willing to adhere to lifelong therapy. Advances in ART continue to shift the therapeutic risk-benefit balance to earlier treatment. Improvements in potency, toxicity and tolerability, and pill burden allow for durable viral suppression for most patients.

The risks associated with ART have decreased, whereas concerns regarding the risks of long-standing untreated viremia have increased. Uncontrolled HIV replication and immune activation lead to a chronic inflammatory state, resulting in end-organ damage and comorbid conditions not previously thought to be associated with HIV infection. Several studies have shown that the life span of those with HIV infection still falls short of that of the general population, even at higher CD4 cell counts.3–6 This life span decrease is related to serious, non-AIDS events attributed to chronic immune activation and the potentially permanent immune damage associated with prolonged immune depletion. In several data sets,3–8 non-AIDS events were associated with elevated levels of viral replication and markers of immune activation and coagulation (including D-dimer, interleukin 6, or high-sensitivity C-reactive protein). Mortality from non-AIDS events now exceeds that of AIDS-defining opportunistic diseases in individuals receiving effective ART.9,11

The strength of evidence supporting initiation of therapy increases as CD4 cell count decreases. In a cohort of 17,517 asymptomatic HIV-infected persons, initiating ART at a CD4 cell count greater than 500/µL decreased mortality by 94%, and initiating it at a CD4 cell count between 351 and 500/µL decreased mortality by 69%, although the numbers of deaths were low in both groups. The majority of deaths were from non-AIDS conditions.10 In an analysis of 62,760 persons in 12 cohorts, reduction in death was 23% and 45% for those beginning therapy with a CD4 cell count greater than 500/µL and 350 to 500/µL, respectively.12

Data from prospective observational cohorts and clinical trials demonstrate worse outcomes among patients who begin receiving ART at CD4 cell counts less than 350/µL or who have symptomatic HIV disease.1 Among 24,444 patients from 18 cohorts, there was no additional benefit from initiating therapy at CD4 cell counts of 451 to 550/µL compared with 351 to 450/µL. However, this analysis included only persons who began receiving ART at less than 550/µL.13 A randomized trial addressing the timing of initiation of therapy is under way. Indicators of rapid progression of disease, such as high HIV-1 RNA and rapid CD4 cell count decline, are recognized as reasons to initiate ART regardless of CD4 cell count.1 Older age is also associated with higher risk of AIDS and non-AIDS-related deaths. Pregnant women should be treated at least by the second trimester and therapy continued after birth.5,10,14–18

Special Considerations
HIV increases the risk of liver-related mortality in those with hepatitis B virus (HBV).19 Hepatitis B infection should not be treated with lamivudine or emtricitabine alone. If tenofovir is contraindicated, entecavir should be added.20 The durability of entecavir is compromised by previous HBV treatment failure with regimens including emtricitabine or lamivudine.21 Flares of hepatocellular inflammation may occur when therapy with agents active against HBV is discontinued or when HBV resistance to lamivudine or emtricitabine emerges in patients receiving these agents without tenofovir or entecavir.22,23 If ART must be interrupted, patients should be closely monitored for HBV reactivation.24

Patients with HIV–hepatitis C virus (HCV) coinfection progress to end-stage liver disease more rapidly than do HCV monoinfected patients.25 Clearance of HCV is associated with regression of liver fibrosis and a reduced risk of ART-related hepatotoxicity.26 In one study, abacavir with ribavirin was associated with a reduced rate of sustained HCV virologic response.27 Zidovudine, didanosine, and stavudine have overlapping hematologic and hepatic toxicities with current HCV therapy.28 Patients with HCV coinfection are at increased risk of hepatotoxicity, and certain ART regimens may require dose adjustment (see “Monitoring” section). Current HCV therapy has a higher probability of sustained HCV virologic response with HCV genotype 2 or 3; therefore, for patients with a high CD4 cell count and no imperative to begin ART, HCV treatment before ART may avoid cumulative drug toxicity and drug interactions.29

Renal disease ranges from HIV-associated nephropathy, to HIV-associated immune complex kidney disease, to
thrombotic microangiopathy. In 5 cross-sectional cohort studies, 5.5% of patients had stages 3 to 5 chronic kidney disease (estimated glomerular filtration rate [eGFR] <60 mL/min for more than 3 months). Older patients, blacks, persons with lower CD4 nadirs, and those with diabetes or hypertension have a higher risk of developing chronic kidney disease.20,30 Albuminuria and eGFR less than 60 mL/min per 1.73 m² are independently associated with an increased risk of cardiovascular events.31 Tenofovir is associated with a decrease in GFR and tubular dysfunction; both indinavir (about 4% of patients)32 and atazanavir33 (uncommonly) are associated with nephrolithiasis. All nRTIs except abacavir may require dose adjustments according to the GFR.

Uncontrolled HIV infection is associated with increased cardiovascular risk.34 In a multivariate analysis involving 70 357 (487 HIV-infected and 69 870 HIV-uninfected) subjects, elevated high-sensitivity C-reactive protein and HIV were independently associated with acute myocardial infarction. With both risk factors, acute myocardial infarction risk increased greater than 4-fold.35 There were strong associations between overall mortality or cardiovascular disease and specific biomarkers. Although ART reduces the level of these biomarkers, they remain elevated compared with those of HIV-uninfected individuals. The clinical utility of these biomarkers for initiation or monitoring therapy is unknown. Modifiable cardiovascular risk factors should be aggressively addressed in all persons with HIV infection.

In a randomized controlled trial of when to initiate ART for patients with active opportunistic infections (excluding tuberculosis [TB]), early initiation (median, 12 days after presentation) reduced death or AIDS progression by 50% compared with beginning ART after the completion of opportunistic infection treatment.36 A South African randomized controlled trial including patients with TB and HIV demonstrated that initiating ART within 2 months of beginning tuberculosis treatment decreased mortality by 56% compared with initiating ART after completion of TB treatment.37 Immune reconstitution inflammatory syndromes occurred more often with early therapy, but no changes in ART were needed and no deaths were related to immune reconstitution inflammatory syndromes. Consideration must be given to the potential for drug interactions among therapies for opportunistic infections and ART.38,39

Patients who present with symptomatic primary HIV infection may progress more rapidly than those who present without symptoms.40,41 Antiretroviral therapy reduces the extremely high viral loads in primary infection and may reduce transmission.42,43 For patients presenting with asymptomatic primary infection, there are insufficient data for a recommendation on whether to treat immediately or defer; however, an analysis of 3019 seroconverters showed a 78% reduction in mortality when ART was initiated rather than delayed.12 Antiretroviral therapy reduces HIV transmission.44 Widespread use of ART during pregnancy has nearly eliminated mother-to-child transmission in the developed world.45,46 A meta-analysis concluded that ART also decreases the risk of HIV transmission to uninfected partners in HIV-serodiscordant heterosexual couples.43 and a cohort study of 3381 heterosexual serodiscordant couples showed a 92% reduction in transmission when ART was used by the infected partner.47 Another cohort study showed a strong association between increased ART coverage, decreased community plasma viral load, and decreased HIV incidence among injection drug users.48 Some mathematic models suggest that more aggressive ART coverage could reduce the incidence of new HIV infections49–51; some field data also support this.42,52

Recommendations
Patient readiness for treatment is a key consideration when deciding when to initiate ART. There is no CD4 cell count threshold at which initiating therapy is contraindicated (BIIa). Initiation of therapy is recommended (TABLE 1) for symptomatic patients with established disease, regardless of CD4 cell count (AIIa), and for asymptomatic individuals with CD4 cell counts less than or equal to 500/µL (AIIa for <350/µL, AIIa for ≤500/µL). Treatment should be considered for asymptomatic individuals with CD4 cell counts greater than 500/µL (CIIH). Therapy is recommended regardless of CD4 cell count in the following settings: increased risk of disease progression associated with a rapid decline in CD4 cell count (ie, >100/µL per year) or a plasma HIV-1 RNA level greater than 100 000 copies/mL (AIIa); older than 60 years (BIIa); pregnancy (at least by the second trimester) (Ala); or chronic HBV or HCV coinfection (BIIa), although for patients with HCV genotype 2 or 3 and high CD4 cell counts, an attempt to eradicate HCV may be undertaken before ART is initiated (BIII); HIV-associated kidney disease (BIIa), avoiding drugs with potential adverse effects on the kidney (tenofovir, indinavir, atazanavir), if possible (AIIa); high cardiovascular risk (BIIa), modifiable risk factors for cardiovascular disease should be aggressively managed (Ala); opportunistic infections, including tuberculosis, with attention to drug interactions and the potential for immune reconstitution inflammatory syndromes (Ala); and symptomatic primary HIV infection to prevent rapid progression, to preserve immune function, and to limit ongoing transmission from this high-risk population (BIIa).52 Once initiated, ART should be continued, except in the context of a clinical trial (Ala). Therapy should be considered where there is a heightened risk of HIV transmission (ie, HIV-serodiscordant couples) (BIIa), without supplanting traditional prevention approaches. Risk reduction counseling should be a routine part of care at each patient-clinician interaction.54

WHAT TO START
Selecting an initial regimen has long-standing consequences for future therapy. The initial regimen should be individualized according to resistance testing results and predicted virologic efficacy, tox-
Antiretroviral Treatment of Adult HIV Infection

Abbreviation: HIV, human immunodeficiency virus.

On either the association or a possible mechanism.

Lamivudine and emtricitabine are each well tolerated and select for the M184V mutation, which confers high-level resistance to both drugs but enhances the activity of tenofovir. Both are active against HBV but should only be used in combination with a second HBV-active drug when treating HIV-HBV coinfected patients. The role of zidovudine in initial regimens is limited by tolerability issues, as well as increased risk for lipodystrophy and hyperlipidemia compared with tenofovir. Stavudine and dideoxynucleosides are not recommended for initial therapy because of increased toxicity of each. Combination regimens including 3 or 4 nRTIs alone are not recommended because of suboptimal virologic activity and increased toxicity.

Nonnucleoside Reverse Transcriptase Inhibitors

Several studies have shown consistently high and sustained rates of viral suppression with efavirenz in the initial regimen. Efavirenz was virologically superior to ritonavir-boosted lopinavir (lopinavir/ritonavir) and comparable to atazanavir/ritonavir and raltegravir. In AIDs Clinical Trials Group A5142, 2 other studies, lopinavir/ritonavir showed better CD4 cell count responses and less drug resistance after virologic failure than efavirenz. Efavirenz is associated with rash and central nervous system adverse effects and should not be used during the first trimester of pregnancy or in women of childbearing age trying to conceive or not using effective and consistent contraception. Efavirenz is an inducer of cytochrome P450, and potential drug interactions are an important consideration. Baseline genotypic testing is important when considering nonnucleoside reverse transcriptase inhibitors (NNRTI) use. Primary NNRTI resistance rates vary from approximately 8.1% in the United States to 2.3% in Europe. Nevirapine was inferior to atazanavir/ritonavir (each combined with tenofovir plus emtricitabine) in a randomized controlled trial restricted to women and men.
with CD4 cell counts less than 250/µL and 400/µL, respectively. Nevirapine was similar virologically to lopinavir/r (again, each with tenofovir/emtricitabine) in a randomized trial of 500 African women with CD4 cell counts less than 200/µL. However, drug discontinuation because of adverse events was higher among nevirapine recipients. Serious hepatic events have been described within the first several weeks of initiation of nevirapine-based therapy but are less frequent if nevirapine is restricted to pretreatment CD4 cell counts less than 250/µL (women) or less than 300/µL (men). They are generally managed with inpatient observation and supportive treatment, and occasionally require admission to the intensive care unit. In some cases, they may be fatal. A summary of the antiretroviral treatment options is presented in Box 1, along with details about their configuration and contraindications, and considerations for resistance and adherence.
therapy, once-daily and twice-daily lopinavir/r in combination with tenofovir plus emtricitabine achieved comparable rates of plasma HIV-1 RNA levels less than 50 copies/mL at 48 weeks, with similar rates of moderate to severe drug-related diarrhea. Other major adverse effects of lopinavir/r include insulin resistance and hyperlipidemia.

Twice-daily fosamprenavir/r and lopinavir/r, both administered with abacavir plus lamivudine, had comparable rates of virologic suppression and adverse events at 48 and 144 weeks. Once-daily vs twice-daily fosamprenavir/r did not differ in rates of virologic suppression.

Saquinavir/r was compared with lopinavir/r, both with tenofovir plus emtricitabine, resulting in rates of viral suppression at 48 weeks of about 65% for each regimen; however, the statistical power of this study was limited by small sample size and short length of follow-up. Triglyceride levels were higher in the lopinavir/r arm. Although this was possibly a class effect, the Food and Drug Administration has issued a warning of a potential risk for QT-interval prolongation with saquinavir/r.

Hepatic transaminase elevations can occur with any of the above regimens, especially in patients with underlying liver disease. Cumulative exposure to indinavir/r, lopinavir/r, and fosamprenavir/r (but not saquinavir/r) has also been associated with an increased risk of cardiovascular events. If possible, these drugs are best avoided in patients with elevated cardiovascular risk. Data concerning cardiovascular risk associated with atazanavir/r or darunavir/r are pending.

**Integrase Strand Transfer Inhibitors**

Raltegravir and efavirenz, each combined with tenofovir and emtricitabine, showed similar high virologic efficacy during 192 weeks. Raltegravir is well tolerated and has a favorable lipid and drug interaction profile; however, it is dosed twice daily and has a relatively low genetic barrier for selection of resistance mutations.

Raltegravir is considered by some as less attractive for initial therapy because it is particularly useful for patients with drug-resistant virus.

**Entry Inhibitors**

The CC chemokine receptor 5 (CCR5) inhibitor maraviroc was compared with efavirenz, both in combination with zidovudine plus lamivudine, in 633 subjects with CCR5-tropic virus and no evidence of resistance to the study drugs. At 48 weeks, HIV-1 RNA less than 50 copies/mL was achieved in 65% and 69% of maraviroc and efavirenz recipients, respectively. The results did not meet prespecified criteria for noninferiority for maraviroc. Through 48 weeks, more participants discontinued maraviroc because of lack of efficacy (11.9% and 4.2%, respectively), whereas fewer participants discontinued maraviroc because of toxicity (4.2% and 13.6%, respectively). Follow-up results at 96 weeks demonstrated durable responses in both groups. Reanalysis of the results with a more sensitive tropism assay or with a genotype-based approach suggested that the differences between treatment arms could be attributed to misclassification of tropism in some patients by the older assay. If only subjects with R5 virus at entry were considered, maraviroc appeared similar to efavirenz in antiretroviral activity. Maraviroc has not been evaluated extensively with other nRTI backbones in initial therapy.

**Recommendations**

Fixed-dose combinations are recommended when possible for convenience. Tenofovir plus emtricitabine is the recommended nRTI combination in initial therapy (A1a). If tenofovir plus emtricitabine cannot be used, abacavir plus lamivudine may be used as an alternative when HLA B*5701 testing results are negative, keeping in mind abacavir’s lower efficacy at high viral loads (A1a). Zidovudine plus lamivudine should be reserved for instances in which neither tenofovir nor abacavir can be used. Three or 4 nRTIs alone are not recommended for initial therapy (A1a). Efavirenz (A1a), atazanavir/r (A1a), darunavir/r (A1a), or raltegravir (Ala) is recommended as the third component of an initial regimen. More evidence is available for efavirenz and atazanavir/r than for third-line therapy. Patients who experienced CD4 cell count increases to levels above these thresholds with undetectable viremia as a result of previous ART safely switched to nevirapine therapy. The efficacy in initial therapy of etravirine, a newer NNRTI, has not yet been reported.
for darunavir/ritonavir or raltegravir. Lopinavir/ritonavir, fosamprenavir/ritonavir, and maraviroc are alternative third-component choices (Ala). Neither saquinavir/ritonavir nor unboosted PIs, including atazanavir, are recommended for initial therapy (Bla). Nevirapine should be used as an alternative initial therapy only with pretreatment CD4 cell counts less than 250 µL (women) or less than 400 µL (men) (BIII). Considerations for initial therapy in patients with specific conditions are summarized in Table 2.

**MONITORING**

Effective therapy should result in suppression to less than 50 copies/mL (polymase chain reaction) or 75 copies/µL (branched DNA) by 24 weeks, regardless of previous treatment experience. Frequent HIV-1 RNA monitoring is recommended during the first year of ART to detect failure.108 Testing of HIV-1 RNA should be repeated 2 to 8 weeks after initiation, every 4 to 8 weeks until suppressed, and then every 3 to 4 months for at least the first year. CD4 cell counts should be monitored at least every 3 to 4 months after initiation of therapy, especially among patients with counts less than 200 µL, to determine the need for continuing opportunistic infection prophylaxis.107,108 In a EuroSIDA study, patients who maintained stable and fully suppressive ART for 1 year had a low chance of experiencing treatment failure in the ensuing months.109 Therefore, once viral replication is suppressed, monitoring intervals may be extended up to every 6 months among patients who remain virologically suppressed and have CD4 cell counts greater than 350 µL. More frequent monitoring is required for patients who have changed therapy because of virologic failure.110

Changes in assay methodology may result in detectable viral load in individuals with previously undetectable viremia.111,112 Detection artifacts have also been attributed to specific plasma processing practices.113 New assays may soon be available with a lower limit of 20 copies/µL; however, the clinical implications of viremia between 20 and 50 copies/µL are not yet clear. Confirmed viral load rebound on 2 separate tests at least 2 to 4 weeks apart should prompt a careful evaluation of regimen tolerability, drug-drug interactions, and patient adherence.

The prevalence of transmitted drug resistance varies in resource-rich societies from 8% to 16%.75,76,114 Baseline ge-

*Details, cautions, considerations, and supporting data are described in the text. Levels of evidence are described in the eBox (available at http://www.jama.com). In HLA B*1501-negative patients; has been associated with increased risk of myocardial infarction. Lower efficacy in patients with >100,000 copies/µL of HIV RNA at baseline (see text).
notropic testing is recommended for all treatment-naive patients.51 For confirmed virologic failure, resistance testing is essential and should be performed while the patient is receiving the failing regimen, when possible. If the trajectory of HIV-1 RNA reduction is not optimal after a new regimen, archived mutations or minority variants may emerge. Minority variants not detected by current resistance testing have been associated with an increased risk of virologic failure; however, the assay thresholds that identify patients at greatest risk of experiencing poor outcomes have not been defined.40,115-119 Tropism testing before use of a CCR5 antagonist is essential because this class has no activity against CX chemokine receptor 4 or dual-tropic viruses.101 Improvement in tropism assay methodology may further facilitate the clinical use of CCR5 antagonists.101,120

The frequency of monitoring for ART toxicity depends on the known toxicities of specific drugs and underlying comorbidities. Monitoring may occur every 2 to 8 weeks after initiation of therapy, decreasing to every 6 to 12 months after stabilization of HIV disease.108,121

Assessment of renal function should occur before initiation and during ART, in particular when tenofovir is used, allowing avoidance, dose modification, or timely substitution of another drug when appropriate.

The recommendations and algorithms of the National Osteoporosis Foundation122 and the World Health Organization fracture risk assessment tool123,124 are useful for the assessment of risk and prevention of osteoporotic fractures; however, these tools have not been specifically validated in the HIV-infected population. Vitamin D deficiency is common in the setting of HIV infection and may be associated with ART use.123 Monitoring of vitamin D levels may be of benefit.125-127

Hepatic, cardiovascular, and renal complications may be associated with uncontrolled HIV replication. Clinical and laboratory assessment of relevant comorbid conditions should be performed before initiation of treatment and during follow-up.108,121 Cardiovascular disease risk should be assessed by available tools. The Framingham risk algorithm may be the most appropriate but may underestimate cardiovascular disease risk in the setting of HIV infection.126 Guidelines for the prevention and management of metabolic complications and noninfectious comorbidities in HIV infection are available.108,121

Therapeutic drug monitoring remains controversial.120 When assays are performed by a quality-assured laboratory, monitoring of PI and NNRTI levels may be useful in pregnant women, children, and patients with renal or liver impairment to minimize overexposure and adverse effects, manage potential drug-drug interactions, or evaluate virologic failure in the absence of resistance. As stated, HLA-B*5701 screening can identify patients at risk for abacavir-associated hypersensitivity.99

Recommendations

Plasma HIV-1 RNA levels should be monitored frequently when treatment is initiated or changed for virologic failure (AIIa) until they decrease below detection limits and regularly thereafter (BIII). Once the viral load is suppressed for a year and CD4 cell counts are stable at 350/µL or greater, viral load and CD4 cell counts can be monitored at intervals of up to 6 months in patients with dependable adherence (CIII). Baseline genotypic testing for resistance should be performed in all treatment-naive patients (AIIa) and in cases of confirmed virologic failure (Ala). HLA-B*5701 haplotype screening should be performed in any patient for whom abacavir is considered (AIIa). Assessment of viral tropism is recommended before using maraviroc (Ala). Therapeutic drug monitoring is not recommended in routine care; however, selected patients might benefit from this intervention (CIII).

WHEN TO CHANGE AND WHAT TO CHANGE

Changing for Virologic Failure

The virologic goal of treatment for first- and multiple-regimen failure is to achieve a plasma HIV-1 RNA level below the limit of detection of the most sensitive assays available. With the availability of new drugs and regimens, this goal now is achievable, even in most patients with multiregimen failure.130-132 Reasons for viral rebound after complete suppression, such as poor adherence, drug-drug interactions, concurrent infections, and recent vaccinations, should be considered before the regimen is changed. Testing for an isolated detectable viral load should be repeated to exclude measurement error or self-resolving low-level viremia.1 Stage of HIV disease, nadir and current CD4 cell count, comorbidities, treatment history, current and previous drug resistance tests, and concomitant medications with potential for interactions should be considered when the new regimen is designed. Ideally 3, but at least 2, fully active drugs should be included and drugs from new classes should be considered. The toxicities of stavudine, didanosine, and to a lesser extent zidovudine make their use problematic, and they should be used only when options are limited.

Initial Failure of NNRTI-Based Regimens. Once failure has been confirmed, an NNRTI-containing regimen should be discontinued as soon as possible to minimize the selection of additional mutations. Initial NNRTI failures traditionally have been treated with 2 active nRTIs plus a PI/r, but raltegravir, maraviroc, and etravirine now provide additional options. According to potency and high genetic barrier, the inclusion of a PI/r should be considered whenever possible, but when not possible, an agent from a new class should be considered. Treatment-experienced patients receiving etravirine and darunavir/r plus an optimized background regimen had better virologic responses than those receiving placebo plus background regimen, with comparable tolerability at 48 weeks.133

Initial Failure of PI/r Regimens. Resistance to the PI/r component does not always emerge when regimen failure is detected, allowing the same drug or another in the PI class to be used in the next regimen. For early failures, strategic sequencing of PIs should be considered. If some degree of PI resistance exists, darunavir/r is likely to be preferred over lopinavir/r or tipranavir/r because of its superior tolerability and toxicity pro-
file, as well as problematic drug interactions associated with tipranavir/r. If not previously used, an NNRTI may be included, provided that potential drug interactions are considered. Whenever possible, a new antiretroviral regimen should contain at least 2 fully active drugs.

**Multidrug (Including PI and NNRTI)**

Resistance. In this setting, 3 active drugs, including new classes of agents (integrate strand transfer inhibitors or entry inhibitors), should be used. Individuals with multidrug-resistant virus usually benefit from a PI/r with activity against resistant strains, such as darunavir/r or tipranavir/r. Etravirine can be paired with darunavir/r (but not tipranavir/r) and may be of value, depending on the number of NNRTI mutations present. Enfuvirtide may be an option if no other new class can be used, despite the inconvenience of subcutaneous injection and injection site reactions. Dual-boosted PIs are not recommended. Lamivudine or emtricitabine is sometimes included to maintain the M184V mutation and decrease viral fitness, but there is no new evidence to support this approach. Another theoretically beneficial strategy is to use zidovudine to prevent the emergence of the K65R mutation in the presence of thymidine analogue mutations when using tenofovir in patients in whom nRTI-containing regimens are failing. However, no clinical benefit has been shown for this approach.

**Changes for Toxicity, Tolerability, or Convenience**

Single-agent switches to decrease toxicity, avoid drug interactions, or improve convenience and adherence are possible, provided the potency of the regimen is maintained and drug interactions are managed. Although some studies have shown maintenance of virologic suppression with PI/r monotherapy as a simplification strategy, other studies have shown higher rates of failure, especially in the central nervous system, than with a combination including 2 nRTI plus a PI/r. Therefore, PI/r monotherapy is not recommended, except in exceptional circumstances when other drugs cannot be considered for reasons of toxicity/tolerability. Delaying switches when adverse effects persist may affect adherence and facilitate the emergence of resistance.

**Simplification**

It may be desirable to switch to an equally effective regimen with fewer drugs or lower pill burden. Not all switches, even with a drug from a new class, are successful because the activity of the accompanying drugs in the regimen is a key determinant of outcome. Continuing lopinavir/r was virologically better than switching to raltegravir in patients with extensive previous 3-class ART experience and pre-existing nRTI resistance. With raltegravir, it is important to maintain a strong ART backbone, usually including a PI/r. Two smaller studies found that raltegravir was safe, well tolerated, and virologically similar when substituted for enfuvirtide in patients with multidrug-resistant HIV-1.

Once-daily darunavir 800 mg/ritonavir 100 mg was noninferior to twice-daily darunavir 600 mg/ritonavir 100 mg in an open-label study in treatment-experienced patients. Dual therapy strategies intended to take advantage of drug interactions such as the combination of unboosted atazanavir and raltegravir are still experimental and are not recommended for clinical practice. For patients with virologic suppression who were receiving a boosted or unboosted PI-based regimen, switching to a once-daily regimen containing atazanavir provided better maintenance of virologic suppression, comparable safety, and improved lipids through 48 weeks compared with continued unmodified therapy.

Treatment interruptions should be avoided. Interruptions, such as those for planned surgeries or severe toxicities in patients without options for switching, should consider the different half-lives of the regimen components; drugs should be discontinued in a staggered manner (or a PI/r temporarily substituted) when an NNRTI is a component.

**Recommendations**

Maintenance of regimen potency is the objective when switching ART regimens. Virologic failure of an initial regimen (confirmed measurable viremia) should be identified and treated as early as possible with at least 2 fully active drugs (Ala) to avoid the accumulation of resistance mutations. For NNRTI failures, the new combination usually should include a PI/r or an agent from a new class (Ala) if a PI/r is not possible. Etravirine may be a useful component of a new regimen for NNRTI failure but must be supported by a potent combination including a PI/r (Ala). Depending on the resistance profile and options available, inclusion of agents from new drug classes (raltegravir or maraviroc) should be considered (BIIb). Mono-therapy with a PI/r should be avoided unless other drugs cannot be considered for reasons of toxicity/tolerability (Ala).

Design of a new regimen should consider previous drug exposure, previous resistance profile, drug interactions, and history of intolerance/tolerance (CIII). Treatment interruptions should be avoided, except in the context of controlled clinical trials (Ala). Elective treatment interruptions should consider the different half-lives of the regimen components, with stopping the drugs in a staggered manner when an NNRTI is a component (CIII).

**CONCLUSIONS AND FUTURE DIRECTIONS**

Increasing evidence that insidious damage occurs during “asymptomatic” HIV infection underscores the potential benefit of ART, even when the risk of traditional AIDS-defining diseases is relatively low. The prominence of non-AIDS events as a major cause of morbidity and mortality in those with ongoing HIV replication suggests that early ART initiation may further improve the quality and length of life for persons living with HIV. The strategic use of newer drugs can improve tolerability, as well as provide durable and potent viral suppression in initial and subsequent therapy.

However, far too many HIV-infected persons present for medical care with advanced disease, both in wealthy and resource-limited settings. Universal voluntary HIV testing, comprehensive pre-
viation services, and early linkage to care and treatment are necessary to ensure that advances in ART are made available during earlier disease stages. Advances in ART have shown that AIDS, as traditionally defined, can be prevented. One of the greatest challenges is that full implementation of these guidelines will require addressing social and structural barriers to diagnosis and care, as well as the pervasive stigma and discrimination associated with an HIV diagnosis.

Analysis of data: Thompson, Cahn, Montaner, Rizzardi, Telenti, Gatell, Günthard, Hammer, Hirsch, Reiss, Richman, Volberding, Yeni, Schooley. Drafting of the manuscript: Thompson, Aberg, Cahn, Rizzardi, Telenti, Günthard, Hirsch, Jacobson, Reiss, Richman, Volberding, Schooley. Critical revision of the manuscript for important intellectual content: Thompson, Aberg, Cahn, Montaner, Rizzardi, Telenti, Gatell, Günthard, Hammer, Hirsch, Reiss, Richman, Volberding, Yeni, Schooley. Obtained funding: Jacobsen, Volberding. Administrative, technical, or material support: Montaner, Günthard, Hammer, Jacobsen, Reiss, Richman, Volberding, Schooley. Study supervision: Thompson, Cahn, Telenti, Hamer, Schooley. Financial Disclosures: Dr Thompson reported receiving research grants awarded to AIDS Research Consortium of Atlanta from Abbott Laboratories, Avexa, Boehringer Ingelheim Pharmaceuticals, Bristol-Myers Squibb, Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, Progenics Pharmaceuticals, Serono, Syngene, and Tobira Therapeutics; and has served on an endpoint adjudication committee for Schering-Plough; has been a recipient of a research grant from Merck; and has been a coprincipal investigator for phase III trials. Dr Cahn reported receiving research grants from Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, Progenics Pharmaceuticals, Schering-Plough, and Tobira Therapeutics; has received an unrestricted research grant from Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, Schering-Plough, Theratechnologies, and Viiv Healthcare; has served on an advisory board for Boehringer Ingelheim Pharmaceuticals, Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, Progenics Pharmaceuticals, Schering-Plough, and Tobira Therapeutics; and has served as an investigator for Astra, Boehringer Ingelheim Pharmaceuticals, Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, Progenics Pharmaceuticals, Schering-Plough, and Tobira Therapeutics; and has received honoraria for speaking engagements from Abbott Laboratories, Bristol-Myers Squibb, Boehringer Ingelheim Pharmaceuticals, Gilead Sciences, GlaxoSmithKline, and Tobira Therapeutics. Dr Montaner reported receiving research grants from, and served as an ad hoc advisor or consultant to, Abbott Laboratories, Gilead Sciences, Boehringer Ingelheim Pharmaceuticals, Bristol-Myers Squibb, Cato Research Canada, ConjuChem Biotech, Gilead Sciences, GlaxoSmithKline, Hoffmann-La Roche, Johnson & Johnson, Merck Canada, Merck Frosst Laboratories, Pfizer Cambridge, Theratechnologies, and Tobira Pharmaceuticals and has served on an endpoint adjudication committee for Schering-Plough. Dr Rizzardi reported receiving research grants from Janssen and Merck & Sharp & Dohme. Dr Telenti reported receiving research grants or honoraria for lectures from Abbott Laboratories, Boehringer Ingelheim Pharmaceuticals, Bristol-Myers Squibb, Gilead Sciences, GlaxoSmithKline, Pfizer, Merck, and Tobira Therapeutics. Dr Richman reported being a consultant to a number of pharmaceutical companies, including Abbott Laboratories, Boehringer Ingelheim Pharmaceuticals, Gilead Sciences, GlaxoSmithKline, Hoffman-La Roche, Johnson & Johnson, Merck, Pfizer, Progenics Pharmaceuticals, Schering-Plough, Theratechnologies, and Tobira Therapeutics; has served on an endpoint adjudication committee for Schering-Plough; has been the recipient of a research grant from Merck; and has been a coprincipal investigator for phase III trials. Dr Hirsch reported being a consultant to a number of pharmaceutical companies, including Abbott Laboratories, Boehringer Ingelheim Pharmaceuticals, Gilead Sciences, GlaxoSmithKline, Hoffman-La Roche, Johnson & Johnson, Merck, Pfizer, Progenics Pharmaceuticals, Schering-Plough, Theratechnologies, and Tobira Therapeutics; and has served as a scientific advisor to Abbott Laboratories, Boehringer Ingelheim Pharmaceuticals, Bristol-Myers Squibb, Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, Roche, Tobira Laboratories, and Viiv Healthcare. Dr Yeni reported receiving scientific grants from Abbott Laboratories, Bristol-Myers Squibb, Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, and Roche Laboratories. Dr Schooley reported serving as a consultant to Achillion Pharmaceuticals, Anadyr Pharmaceuticals, Ardea Biosciences, Gilead Sciences, GlaxoSmithKline, Inhibitex, ItherX, Johnson & Johnson, LabCorp, Merck, Myriad Biosciences, Pfizer, TaiMed Biologics, Tanox, Tobira Therapeutics, Vertex Pharmaceuticals, and Viiv; has received grants from Gilead Sciences and Merck; and has stock options for Achillion Pharmaceuticals.

Funding/Support: This work was funded by the International AIDS Society–USA. Panel members serve in volunteer capacities (ie, are not compensated). No private sector or government funding was used to support the effort. The International AIDS Society–USA has received grants for selected CME activities (unrelated to guidelines development) from Abbott Laboratories, Boehringer Ingelheim Pharmaceuticals, Bristol-Myers Squibb, Gilead Sciences, GlaxoSmithKline, Merck, Pfizer, Roche Laboratories, Tobira Therapeutics, and Viiv Healthcare. Grants are pooled such that no single company supports any single effort.

Role of the Sponsor: The International AIDS Society–USA determined the need for updated recommendations, selected the panel members, and provided administrative oversight and financial support.

Online-Only Material: The eTable, eBox, and eFigure are available at http://www.jama.com.

Additional Contributions: We thank Michelle Tayag Valderama, BS, who was compensated as an employee of the International AIDS Society–USA, for administrative support.
