Acute interstitial nephritis caused by lopinavir/ritonavir in a surgeon receiving antiretroviral postexposure prophylaxis

A previously healthy 51-year-old male surgeon sustained a deep hollow-bore needle-stick injury while infiltrating local anaesthetic into a wound. The source patient was HIV seropositive and antiretroviral therapy naive with a CD4⁺ cell count of 613 cells/µl. Postexposure prophylaxis (PEP) was initiated with zidovudine, lamivudine and lopinavir/ritonavir (LPV/r).

Four days after initiating PEP, he developed mild fever and malaise. On day 5, he developed bilateral flank pain and macroscopic haematuria. On day 6, creatinine was 266 µmol/l, urea 8.8 mmol/l, and creatine kinase within normal range. Renal ultrasound showed normal size kidneys and no evidence of nephrolithiasis. On day 7, he stopped the LPV/r as he suspected this drug to be the cause of his renal impairment, whereas zidovudine and lamivudine were continued. His symptoms resolved within 2 days of stopping LPV/r and his creatinine improved to 209 µmol/l on day 8, 123 µmol/l on day 36 and 108 µmol/l on day 77. HIV serology (combination p24 antigen and HIV-1/HIV-2 antibody assay) was negative on days 36 and 77.

We believe LPV/r to be the cause of acute kidney injury (AKI) in this case which, to our knowledge, has not previously been reported [1]. The protease inhibitors that have been associated with AKI include atazanavir, indinavir, ritonavir and saquinavir [2]. AKI associated with ritonavir has only been described with full doses, and not with low doses used for boosting [1,3]. We suspect acute interstitial nephritis as the cause of AKI because of the short latency period relative to PEP initiation, presence of systemic symptoms, haematuria and a positive response following dechallenge of LPV/r [4]. Acute interstitial nephritis has been described with the protease inhibitors indinavir and atazanavir, but there are no studies implicating LPV/r [1,5,6]. However, we are unable to confirm this diagnosis in the absence of a renal biopsy.

Zidovudine has been associated with AKI on the basis of myoglobinuria from rhabdomyolysis [7,8]. The normal blood creatine kinase concentration, and the clinical improvement despite continued zidovudine administration, excluded this diagnosis in our patient. Lamivudine has been reported to cause AKI with Fanconi syndrome, but we excluded lamivudine as a cause because the clinical picture was not compatible and there was clinical improvement despite continued lamivudine administration [9].

Attempting to establish causality in antiretroviral-related AKI can be complex as HIV-infected patients often have multiple comorbidities, use other potentially nephrotoxic drugs, and may have underlying HIV-associated nephropathy. These potential confounding factors were not present in our case of a healthy HIV-uninfected healthcare worker receiving PEP.

Effect of ipilimumab on the HIV reservoir in an HIV-infected individual with metastatic melanoma

Long-lived latently infected resting CD4+ T cells are the main reason why current antiretroviral therapy (ART) is unable to cure HIV infection [1]. Recent work has suggested that the expression of immune checkpoint markers, such as programmed death-1 (PD1), may play a role in viral persistence on ART via either suppression of virus transcription and/or reduced HIV-specific T cell activity [2,3], but the role of cytotoxic T lymphocyte antigen 4 (CTLA-4 or CD152) in HIV persistence on ART is not clear.

Ipilimumab (Yervoy, Bristol-Myers Squibb, New York, New York) is a human immunoglobulin G1 antibody to CTLA-4 that inhibits binding of CTLA-4, expressed on its ligands CD80 and CD86. The drug is used to treat metastatic melanoma and has been associated with multiple changes in immune function thought to enhance antitumor T cell function [4].

In HIV-infected individuals, CTLA-4 expression on CD4+ T cells correlates with HIV disease progression [5], and loss of HIV-specific CD4+ T cell function can be reversed in vivo by CTLA-4 blockade [5–7]. In a simian immunodeficiency virus (SIV) macaque model, CTLA-4 blockade led to an increase in T-cell activation and viral replication [8]. Here, we describe changes in the HIV reservoir in an HIV-infected patient on ART who received ipilimumab for the treatment of metastatic melanoma.

At initiation of ipilimumab treatment in October 2013 for disseminated melanoma, the patient was a 51-year-old man diagnosed with HIV in 1986 and with a CD4+ nadir of 159 cells/µl in 1995. He was on ART since 1996 and plasma HIV RNA was less than 400 copies/ml from 2004 and less than 20 copies/ml from July 2012 (Fig. 1a). He received four doses of ipilimumab 3 mg/kg given at three-weekly intervals.

Whilst receiving ipilimumab, there was no overall change in plasma HIV RNA as measured by the Roche viral load assay [lower limit of detection (LOD) = 20 copies/ml; Fig. 1c]. Using a sensitive single-copy HIV RNA assay (SCA) (LOD = 0.3 copies/ml) [9], there was a cyclical decrease in plasma HIV RNA following each infusion and an overall decline from 60 to 5 copies/ml (Fig. 1c). Given more frequent sampling was performed with the SCA, we believe that longitudinal changes over time were best assessed with this assay.

There was an increase in CD4+ T cells after each infusion (overall change from 610 to 900 cells/µl) (Fig. 1b). This increase was predominantly in total memory (Fig. 1d) and effector memory CD4+ T cells (Fig. 1e). Postinfusion increases in CD4+ T-cell activation were seen as measured by human leukocyte antigen-DR and CD38 and CCR5 expression (Fig. 1f). There were transient increases in CD8+ T cells following the second and third infusions, but no overall change in CD8+ T cell activation (Fig. 1g).

Cell-associated unspliced HIV RNA in sorted CD4+ T cells was quantified with increases observed following the first and second infusions, with a maximum change from baseline of 19.6-fold (Fig. 1h). The changes in cell-associated unspliced HIV RNA was greater than those recently reported, following the administration of the histone deacetylase inhibitors vorinostat [10,11] or panobinostat [12], or following disulfiram [13].

There was no change in cell-associated HIV DNA (Fig. 1i), but any change in the small proportion of cells with HIV DNA containing inducible proviruses [14] may not have been detectable with the assays used here.

Acknowledging the limitations deriving from this being a single case, we speculate the increase in cell-associated unspliced RNA could have been due to mechanisms, including an increase in HIV RNA transcription secondary to blocking the inhibitory effects of CTLA-4 on T cell transcription, similar to that described following ex-vivo anti-PD1 treatment of CD4+ T cells from HIV-infected patients on ART [15]; redistribution or expansion of effector memory CD4+ T cells that may have a higher ratio of cell-associated HIV RNA to HIV DNA [16] (Satish Pillai, San Francisco, UCSF, San Francisco, California, personal communication); or redistribution or expansion of activated T cells including Tregs. The increase in cell-associated unspliced HIV RNA and decline in SCA was intriguing, perhaps mediated by elimination of latently infected CD4+ T cells that were induced to express viral antigens. But the rapidity of the decline in SCA makes this somewhat unlikely.

Blockade of CTLA-4 with ipilimumab in an HIV-infected patient on ART had significant effects on the
Fig. 1. Clinical details and changes and impact of ipilimumab on virological and immunological parameters. (a) An HIV-infected patient on ART who developed metastatic melanoma involving brain, right axilla, mesentery, and small bowel, all managed with surgical resection, underwent four cycles of ipilimumab treatment (dashed lines). The protocol for collection of plasma and peripheral blood mononuclear cells (PBMCs) for assessment of the HIV reservoir was approved by the Human Research and Ethics Committee, Royal Prince Alfred Hospital, Sydney, Australia, and the patient provided written informed consent. Plasma and PBMCs were collected at day −1, +1, and +7 for each cycle (arrows). Changes over the course of treatment are shown for (b) total lymphocyte, and CD4⁺ and CD8⁺ T cells quantified by flow cytometry; (c) plasma HIV RNA measured by the Roche RT-PCR viral load assay (red line, open circles indicate sample below LLOD = 20 copies/ml) and single-copy assay (SCA) (green circles; LLOD = 0.3 copies/ml); (d) the percentage of memory (squares, solid line) and naïve (squares, dashed line); (e) effector memory (circles, solid line) and central memory (circles, dashed line) CD4⁺ T cells and activation markers HLA-DR and CD38 (purple) and CCR5 (pink line) on (f) CD4⁺ and (g) CD8⁺ T cells. (h) Cell-associated (CA) unspliced (US) HIV RNA and (i) HIV DNA were quantified in sorted CD4⁺ T cells using RT-PCR. The LLOD for both assays was 10 copies per million cell equivalents. ART, antiretroviral therapy; LLOD, lower limit of detection; RT, real-time.
total number and phenotype of CD4^{+} T cells and induced a profound increase in cell-associated unspliced HIV RNA with onset after the first dose and was associated with subsequent decline in plasma HIV RNA. Further studies are warranted to determine if ipilimumab could play a role in eliminating latently infected cells in HIV-infected patients on ART.
