Efficacy and Safety of Further Lowering of Low-Density Lipoprotein Cholesterol in Patients Starting With Very Low Levels
A Meta-analysis

Marc S. Sabatine, MD, MPH; Stephen D. Wiviott, MD; KyungAh Im, PhD; Sabina A. Murphy, MPH; Robert P. Giugliano, MD, SM

IMPORTANCE In the Cholesterol Treatment Trialists Collaboration (CTTC), in patients starting with low-density lipoprotein cholesterol (LDL-C) levels of approximately 3.4 mmol/L (131.5 mg/dL), there was a 22% reduction in major vascular events per 1-mmol/L (38.7-mg/dL) lowering of LDL-C. The magnitude of clinical benefit of further LDL-C lowering in patients already with very low LDL-C levels remains debated.

OBJECTIVE To evaluate efficacy and safety of further lowering LDL-C levels in patient populations presenting with median LDL-C levels of 1.8 mmol/L (70 mg/dL) or less.

DATA SOURCES AND STUDY SELECTION The CTTC was used for statin data. For nonstatin therapy, Medline database was searched (2015-April 2018). Key inclusion criteria were a randomized, double-blind, controlled cardiovascular outcome trial of LDL-C lowering with data in populations starting with LDL-C levels averaging 1.8 mmol/L (70 mg/dL) or less.

DATA EXTRACTION AND SYNTHESIS Two authors independently extracted data into standardized data sheets, and data were analyzed using meta-analysis.

MAIN OUTCOMES AND MEASURES The risk ratio (RR) of major vascular events (a composite of coronary heart death, myocardial infarction, ischemic stroke, or coronary revascularization) per 1-mmol/L (38.7-mg/dL) reduction in LDL-C level.

RESULTS In the subgroup of patients from the CTTC meta-analysis of statins with a mean LDL-C in the control arm of 1.7 mmol/L (65.7 mg/dL), 1922 major vascular events occurred and the RR for major vascular events per 1-mmol/L (38.7-mg/dL) reduction in LDL-C was 0.78 (95% CI, 0.65-0.94). For 3 trials of nonstatin LDL-C–lowering therapies added to statins, there were 50 627 patients, the median LDL-C in the control arms ranged from 1.6 mmol/L to 1.8 mmol/L (63 mg/dL to 70 mg/dL), and 9570 major vascular events occurred. Nonstatin therapy lowered LDL-C by 0.3 to 1.2 mmol/L (11 mg/dL to 45 mg/dL), and the RR for major vascular events per 1-mmol/L (38.7-mg/dL) reduction in LDL-C was 0.79 (95% CI, 0.70-0.88). For statins and nonstatins combined, the RR was 0.79 (95% CI, 0.71-0.87; $P < .001$). Low-density lipoprotein cholesterol lowering was not associated with an increased risk of serious adverse events, myalgias and/or myositis, elevation in the level of aminotransferases, new-onset diabetes, hemorrhagic stroke, or cancer.

CONCLUSIONS AND RELEVANCE There is a consistent relative risk reduction in major vascular events per change in LDL-C in patient populations starting as low as a median of 1.6 mmol/L (63 mg/dL) and achieving levels as low as a median of 0.5 mmol/L (21 mg/dL), with no observed offsetting adverse effects. These data suggest further lowering of LDL-C beyond the lowest current targets would further reduce cardiovascular risk.

Published online August 1, 2018.

A series of randomized clinical trials of statin therapy, first of statin vs no statin and then intensive vs less intensive statin therapy, demonstrated successive risk reduction, with experimental arms that achieved progressively lower levels of low-density lipoprotein (LDL) cholesterol.[1] Based on these data, National Cholesterol Education Program guidelines recommended progressively lower LDL-C targets.[2] A meta-analysis of 26 statin trials by the Cholesterol Treatment Trialists Collaboration (CTTC) quantified the magnitude of benefit. There was a 22% relative risk reduction in major vascular events per 1-mmol/L reduction in LDL-C that was consistent across baseline LDL-C levels, even down to less than 2 mmol/L (77.3 mg/dL), although only a small proportion of patients started at such low levels.[3]

We are now in a new era with nonstatin drugs that further lower LDL-C levels and further reduce cardiovascular risk when added to statins. Clinical trials with these drugs afford the opportunity to quantify the clinical benefit of LDL-C lowering and to examine whether it remains consistent even in individuals starting with and achieving lower levels than were examined in the CTTC meta-analysis and lower than current guideline targets. Likewise, they offer the opportunity to explore any signals of harm in patients with LDL-C lowering to such levels.

Key Points

Question Is the clinical benefit of low-density lipoprotein cholesterol (LDL-C) lowering preserved in patient populations starting with LDL-C levels averaging 1.8 mmol/L (70 mg/dL) or less, and is LDL-C lowering safe in such patients?

Findings In this meta-analysis, for statins and nonstatins, the risk of major vascular events was significantly reduced by 21% for each 1-mmol/L (38.7-mg/dL) reduction in LDL-C, which was virtually the same magnitude as seen in the overall Cholesterol Treatment Trialists Collaboration analysis in which the starting LDL-C was nearly twice as high. No adverse safety signal was detected for LDL-C lowering.

Meaning Further lowering of LDL-C beyond the lowest current targets is associated with further reduced cardiovascular risk with no offsetting safety risks.

Methods

This study follows the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines.[4] The CTTC meta-analysis provided data for statin therapy in a subset of patients starting with a mean LDL-C level of 1.7 mmol/L (65.7 mg/dL). We searched the medical literature via Medline database for and analyzed randomized, double-blind, controlled cardiovascular outcome clinical trials of adding LDL-C-lowering therapy to a statin that have published data on patients starting with a mean or median LDL-C level of 1.8 mmol/L (70 mg/dL) or less (a threshold for decision making in guidelines). For further details on the literature search and inclusion and exclusion criteria, see eMethods in the Supplement.

The CTTC outcome of major vascular events comprised of coronary heart death, myocardial infarction, ischemic stroke (if available, otherwise all stroke), or coronary revascularization was used. The risk ratio (RR) per 1-mmol/L (38.7-mg/dL) difference in LDL-C between treatment arms was calculated for each trial. A fixed-effects inverse-weighting model was used to meta-analyze the results. The association between achieved LDL-C and estimated 5-year rate of major vascular events was evaluated using fixed-effects meta-regression analysis of the data from each group (experimental and control). Safety outcomes of interest included serious adverse events, myalgias and/or myositis, elevation in the level of aminotransferases, new-onset diabetes, hemorrhagic stroke, and cancer. Risk ratios and 95% CI were extracted or calculated from raw counts for each trial and meta-analyzed using a fixed-effects inverse-weighting model. Statistical analyses were performed using Comprehensive Meta Analyses, version 3.3.070 (Biostat Inc) and R, version 3.2.2 (R Programming).

Results

In the CTTC meta-analysis of statin therapy,[3] within the subset of patients starting with a mean LDL-C level of 1.7 mmol/L (65.7 mg/dL), the RR for major vascular events per 1-mmol/L (38.7-mg/dL) reduction in LDL-C was 0.78 (95% CI, 0.65-0.94). The literature search identified 32 studies (eFigure in the Supplement), of which data from 3 randomized, double-blind, placebo-controlled clinical trials of nonstatin LDL-C-lowering therapy added to background statin therapy were included in the meta-analysis (**Table 1**). All 3 were secondary prevention trials that enrolled patients with known atherosclerotic cardiovascular disease. Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT)[5] studied ezetimibe in 18 144 patients stabilized after a recent acute coronary syndrome.[5] The median LDL-C in the control arm was 1.8 mmol/L (70 mg/dL). Ezetimibe reduced LDL-C levels by 0.3 mmol/L (13 mg/dL) and the relative risk of major vascular events by 7.5%. Further Cardiovascular Outcomes Research With PCSK9 Inhibition in Patients With Elevated Risk (FOURIER)[6] studied the PCSK9 inhibitor evolocumab in 27 564 patients with stable atherosclerotic cardiovascular disease (either prior myocardial infarction, prior stroke, or symptomatic peripheral artery disease).[6] Among 2034 patients with a baseline LDL-C level less than 1.8 mmol/L (70 mg/dL), the median LDL-C level in the control arm was 1.7 mmol/L (66 mg/dL), and evolocumab reduced LDL-C levels by 1.1 mmol/L (42 mg/dL) and the relative risk of major vascular events by 22%.[7] Randomized Evaluation of the Effects of Anacetrapib through Lipid Modification (REVEAL) studied the cholesteryl ester transfer protein (CETP) inhibitor anacetrapib in 30 449 patients with stable atherosclerotic cardiovascular disease (either prior myocardial infarction, prior stroke or carotid revascularization, prior peripheral artery revascularization, or diabetes with symptomatic coronary heart disease).[8] The median LDL-C level in the control arm was 1.6 mmol/L (63 mg/dL). Anacetrapib reduced LDL-C by 0.3 mmol/L (11 mg/dL) and the relative risk of major vascular events by 7%.

Table 1. Trial Characteristics

Trial	No. of Participants	Type of Intervention	Drug	Achieved LDL-C, mmol/L		Median Duration of Follow-up, y	Overall No. of Major Vascular Events
				Control Arm	Experimental Arm		
CTTC (<2 mmol/L)	NR	HMGCR inhibitor (statin)	Various	1.7[a]	NR	4.9[b]	1922
IMPROVE-IT	18 144	NPC1L1 inhibitor	Ezetimibe	1.8[c]	1.4	6.0	5104
FOURIER (<1.8 mmol/L)	2034	PCSK9 inhibitor	Evolocumab	1.7[d]	0.5	2.1	184

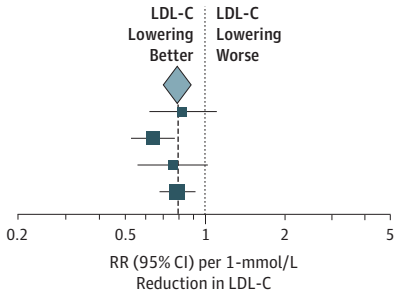
A, Risk ratios (RRs) were generated from fixed-effects models. Size of data markers is weighted based on the inverse variance. I^2 for heterogeneity 0%, $P > .99$. B, Levels of LDL-C in the control arm (square symbols) and experimental arm (arrowheads) in each of the nonstatin trials (trial arms connected by lines). The black line and dashed 95% CI are from a fixed-effects meta-regression. FOURIER indicates Further Cardiovascular Outcomes Research With PCSK9 Inhibition in Patients With Elevated Risk; IMPROVE-IT, Improved Reduction of Outcomes: Vytorin Efficacy International Trial; REVEAL, Randomized Evaluation of the Effects of Anacetrapib through Lipid Modification. To convert LDL-C from millimoles per liter to milligrams per deciliter, multiply by 38.67.

A meta-analysis of the RR for major vascular events from each trial normalized for the LDL-C reduction achieved in that trial is shown in **Figure 1**A. The data from the prior CTTC meta-analysis showed an RR of 0.78 (95% CI, 0.65-0.94) per 1-mmol/L (38.7-mg/dL) lowering of LDL-C for statins. For nonstatin therapies, the RR was 0.79 (95% CI, 0.70-0.88; $P < .001$). Data for the individual components of the composite outcome were consistent (**Figure 2**). The overall effect for statins and nonstatins was an RR of 0.79 (95% CI, 0.71-0.87; $P < .001$).

Trial reports that did not provide the necessary information were excluded. Specifically, Heart Outcomes Prevention Evaluation 3 (HOPE-3) studied rosuvastatin but was excluded because the lowest reported starting LDL-C subgroup was only 2.9 mmol/L (112 mg/dL) or less. Assessment of Clinical Effects of Cholesteryl Ester Transfer Protein Inhibition With Evacetrapib in Patients at a High Risk for Vascular Outcomes (ACCELERATE) studied the CETP inhibitor evacetrapib but was excluded because LDL-C was not measured by β quantification, and it has been shown that in patients receiving CETP inhibitors, both Friedewald estimation and direct LDL-C assays underestimate LDL-C and therefore would overestimate LDL-C reduction. The ODYSSEY Outcomes trial studied

Figure 2. Individual Efficacy Outcomes in Nonstatin Trials

Outcome	Patients With Events, No.		RR (95% CI)
	Experimental Arm	Control Arm	
Major vascular events	4604	4966	0.79 (0.70-0.88)
Coronary heart death	836	891	0.82 (0.62-1.10)
Myocardial infarction	1671	1930	0.64 (0.53-0.77)
Ischemic stroke	737	804	0.76 (0.56-1.02)
Coronary revascularization	3003	3228	0.79 (0.68-0.92)



In this analysis of the individual components of the composite outcome, ischemic stroke was used where available; otherwise all stroke was used. In Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT), per the trial end point definitions, coronary revascularizations were those that occurred at least 30 days after randomization. Patients could have had more than 1 event. The size of the boxes is proportional to the number of events. The horizontal lines represent 95% confidence intervals. LDL-C indicates low-density lipoprotein cholesterol.

Table 2. Safety Outcomes in Trials of Nonstatin Therapy

Safety Outcome	Patients With Event, No.		Meta-analysis Data	
	Experimental Arm	Control Arm	Risk Ratio (95% CI)	*P* Value
Any serious adverse event	12 809	12 836	1.00 (0.98-1.02)	.89
Myalgias or myopathy	116	135	0.85 (0.66-1.08)	.19
Aminotransferase elevation	488	510	0.96 (0.85-1.08)	.48
New-onset diabetes	1272	1320	0.97 (0.90-1.05)	.46
Hemorrhagic stroke	132	118	1.11 (0.87-1.43)	.40
Cancer	1747	1715	1.02 (0.96-1.09)	.55

the PCSK9 inhibitor alirocumab but was excluded because the lowest reported starting LDL-C subgroup was only less than 2.1 mmol/L (80 mg/dL). However, sensitivity analyses that included data extrapolated from these trials did not materially affect the results, with point estimates that shifted by no more than 0.01 (eResults in the Supplement). The plot of achieved LDL-C vs the estimated 5-year rates of major vascular events in the experimental and control arms of the 3 nonstatin trials (Figure 1B) shows a significant association, down to 0.5 mmol/L (21 mg/dL) (β, 0.35; 95% CI, 0.25-0.45; $P < .001$).

In terms of safety, LDL-C lowering was not associated with an increased risk of serious adverse events, myalgias and/or myositis, elevation in the level of aminotransferases, new-onset diabetes, hemorrhagic stroke, or cancer in any of the trials individually or when meta-analyzed (**Table 2** and **Figure 3**).

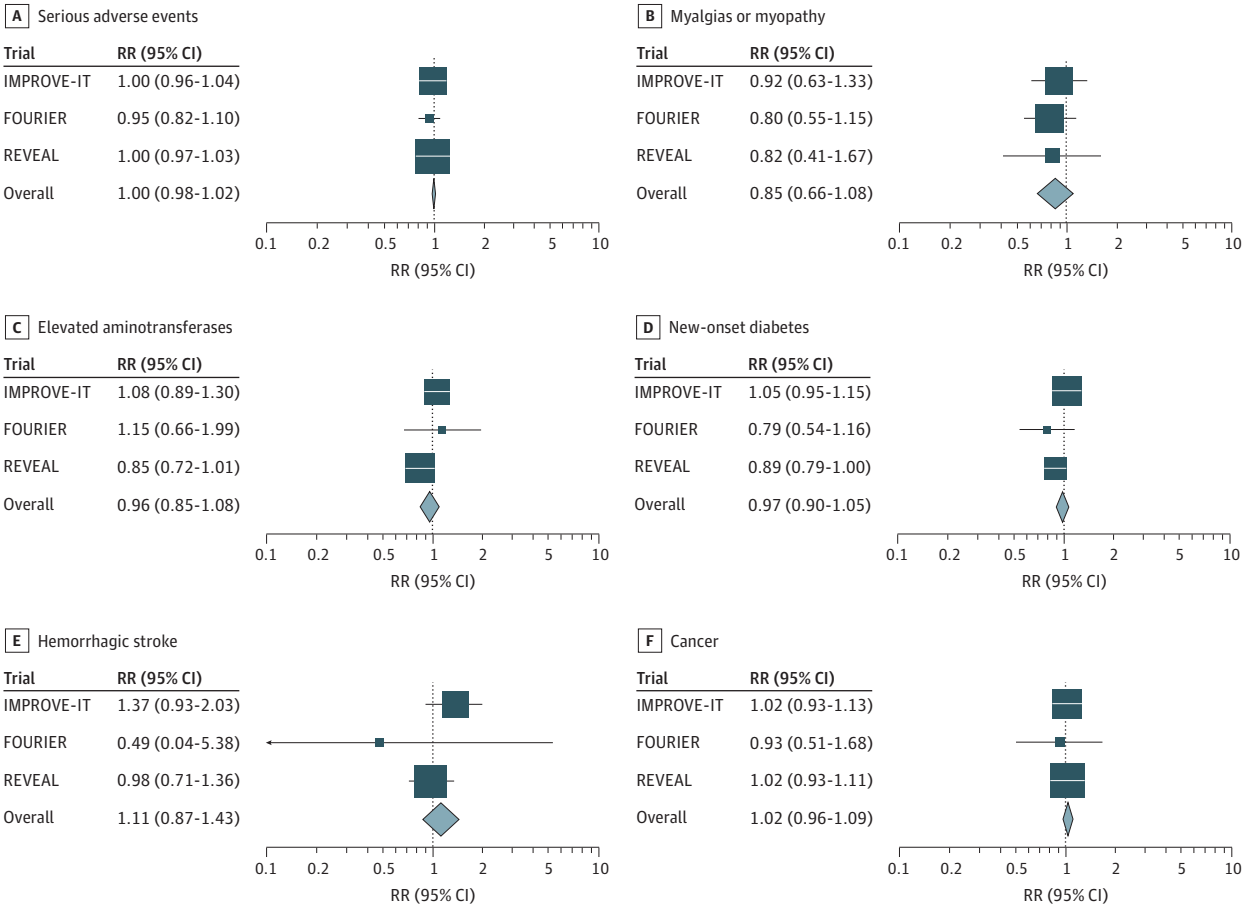
Discussion

Extending observations made with statins, we found consistent clinical benefit from further LDL-C lowering in patient populations starting as low as a median of 1.6 mmol/L (63 mg/dL) and achieving levels as low as a median of 0.5 mmol/L (21 mg/dL). Specifically, when examining 11 492 major vascular events, there was a 21% relative risk reduction per 1-mmol/L (38.7-mg/dL) reduction in LDL-C through this range. This relative risk reduction is virtually the same as the 22% reduction seen in the overall CTTC analysis in which the starting LDL-C was nearly twice as high.[3] Moreover, these data parallel observational data showing progressively greater coronary atherosclerotic plaque regression and progressively lower adjusted risk of major vascular events with progressively LDL-C levels down to less than 0.2 mmol/L (7 mg/dL).[9,10] Furthermore, there was no evidence of an increased incidence of adverse events with lowering LDL-C to such levels. These levels are considerably lower than the targets or thresholds for additional nonstatin LDL-C-lowering therapy in current cholesterol guidelines that, for high-risk patients, range from 1.8 mmol/L to 2.6 mmol/L (70 mg/dL to 100 mg/dL).[11-13]

The clinical benefit per millimoles per liter reduction in LDL-C was virtually identical for statins, ezetimibe, PCSK9 inhibition, and CETP inhibition, despite these drugs having different effects on other risk markers such as high-density lipoprotein cholesterol, lipoprotein(a), and high-sensitivity C-reactive protein. This observation reinforces the notion that the reduction in LDL-C (or more broadly, atherogenic apolipoprotein B–containing particles) is the primary driver of clinical benefit.

Because LDL-C–lowering therapies tend to produce the same relative percentage lowering of LDL-C regardless of starting levels, the absolute lowering of LDL-C and therefore the relative and absolute risk reductions will mathematically be a function of the baseline LDL-C. For example, in patients starting with an LDL-C level of 2.6 mmol/L (100 mg/dL), a 60% decrease in LDL-C (what a PCSK9 inhibitor typically achieves) should lower LDL-C by 1.6 mmol/L (60 mg/dL), reduce the relative risk of major vascular events by 31%, and, assuming a 5-year major vascular event rate of 25% in a secondary prevention population, yield an absolute risk reduction of 7.8%. If the same patients started with an LDL-C level of 1.8 mmol/L (70 mg/dL),

Figure 3. Safety Outcomes in Nonstatin Trials



The size of the boxes is proportional to the weight in the analysis for each trial. The horizontal lines represent 95% confidence intervals. FOURIER indicates Further Cardiovascular Outcomes Research With PCSK9 Inhibition in Patients With Elevated Risk; IMPROVE-IT, Improved Reduction of Outcomes: Vytorin Efficacy International Trial; REVEAL, Randomized Evaluation of the Effects of Anacetrapib through Lipid Modification.

LDL-C should be lowered by 1.1 mmol/L (42 mg/dL) and the relative risk of major vascular events by 23%, which would yield an absolute risk reduction of 5.8%.

However, because there were no offsetting safety concerns with LDL-C lowering through this range, the benefit-risk ratio from a medical perspective should always remain favorable (assuming longer-term safety data of very low LDL-C in larger numbers of individuals are equally reassuring). Assessment of cost-effectiveness is more complicated,[14,15] and whereas statins and ezetimibe are generic, PCSK9 inhibitors are not. If one wishes to target a minimum absolute risk reduction in major vascular events to justify the cost of therapy, a nomogram exists to identify patients based on baseline risk and LDL-C.[16]

Limitations

This analysis included data from a small number of randomized clinical trials with different entry criteria and durations of follow-up. Nonetheless, the risk reduction per 1-mmol/L reduction in LDL-C was remarkably consistent. The cut point of 1.8 mmol/L (70 mg/dL) was post hoc but was selected given the treatment targets cited in prior guidelines.

Conclusions

In summary, there is a consistent relative risk reduction in major vascular events per further reduction in LDL-C in patient populations starting as low as a median of 1.6 mmol/L (63 mg/dL) and achieving levels as low as a median of 0.5 mmol/L (21 mg/dL), with no offsetting adverse effects. These data suggest further lowering of LDL-C thresholds for initiating more intensive therapy, or simply targeting LDL-C at least as low as approximately 0.5 mmol/L or 20 mg/dL, would further reduce cardiovascular risk.
